

CLINICAL IMAGES

Carcinoid syndrome

Habib ur Rehman MBBS

A 72-year-old man was admitted to hospital with congestive heart failure, weight loss and chronic diarrhea. He had flushing of the face and cyanosis, and telangiectasia were present in the cheek area (Figure 1).

A contrast-enhanced computed tomography scan of the liver showed multiple masses with ring enhancement that were compatible with metastases (Figure 2). An echocardiogram showed right-sided dilation of the heart with severe tricuspid regurgitation. The patient's aortic, mitral and pulmonic valves were normal in structure and function. A 24-hour urine collection showed a total output of 5-hydroxyindoleacetic acid of 1515 (normal 0–43) $\mu\text{mol/L}$. A biopsy of the liver with immunostaining for chromogranin and synaptophysin were strongly positive and confirmed a diagnosis of metastatic carcinoid syndrome. The patient died 4 months later.

A carcinoid tumour is a rare neuroendocrinologic malignancy that commonly originates from enterochromaffin cells in the gastrointestinal tract. The rate of incidence of carcinoid tumours has increased from 1.09 cases per 100 000 in 1973 to 5.25 cases per 100 000 in 2004, with a median age at diagnosis of 63 years.¹ This increase has likely resulted from improvements in the classification of such tumours and from more widespread use of certain diagnostic screening tools such as endoscopy. Carcinoid syndrome occurs when cells from the tumour metastasize to the liver and vasoactive substances enter systemic circulation via the hepatic vein. Flushing involving the face and upper trunk are the most prominent cutaneous signs. Telangiectasias may also develop. Flushing may be worsened by the consumption of hot foods and beverages, chocolate, spicy foods, tomatoes, alcohol and cheeses or by emotional stress.² As many as 20% of patients with carcinoid syndrome present with carcinoid heart disease at diagnosis. Echocardiographic abnormalities, commonly involving the tricuspid valve, are found in up to 70% of patients.^{3,4} The median duration of survival is 124 months for patients with neuroendocrine tumours at the grade 1 stage, 64 months for those with grade 2 tumours and 10 months for those with grade 3 or 4 tumours.
